ABSTRACT

The all pairs shortest path problem is a fundamental optimization problem in graph theory. We deal with re-calculating the all-pairs shortest path (APSP) matrix after a minor modification of a weighted dense graph, e.g., adding a node, removing a node, or updating an edge. We assume the APSP matrix for the original graph is already known. The graph can be directed or undirected. A cold-start calculation of the new APSP matrix by traditional algorithms, like the Floyd-Warshall algorithm or Dijkstra's algorithm, needs $O(n^3)$ time. We propose two algorithms for warm-start calculation of the new APSP matrix. The best case complexity for a warm-start calculation is $O(n^2)$, the worst case complexity is $O(n^3)$. We implemented the algorithms and tested their performance with experiments. The result shows a warm-start calculation can save a great portion of calculation time, compared with cold-start calculation.

KEYWORDS

All pairs shortest path; Shortest path problem

1 INTRODUCTION

The Shortest Path Problem is a fundamental optimization problem in graph theory and computer science. It involves finding shortest path between two vertices in a graph such that the sum of the weights of its constituent edges is minimized.

Let $G = (V, E)$ be a graph where:

- V is the set of vertices (nodes),
- $E \subseteq V \times V$ is the set of edges (connections between nodes),
- $w : E \to \mathbb{R}^+ \cup \{0\}$ is a weight function assigning a non-negative weight to each edge.

For a given source vertex $s \in V$ and target vertex $t \in V$, the Shortest Path Problem seeks to find a path P from s to t such that:

$$P = \{v_1, v_2, \ldots, v_k\}, \quad v_1 = s, \ v_k = t,$$

and the total path weight is minimized:

$$\text{minimize: } W(P) = \sum_{i=1}^{k-1} w(v_i, v_{i+1}),$$

where $(v_i, v_{i+1}) \in E$ for $i = 1, 2, \ldots, k - 1$.

The all-pairs shortest path (APSP) problem compute the shortest paths between all pairs of vertices $u, v \in V$. A dense graph is a graph in which the number of edges is close to the maximum possible number of edges for the given number of vertices.

Let $G = (V, E)$ be a graph, where $|V| = n$ is the number of vertices and $|E|$ is the number of edges. A dense graph satisfies:

$$|E| \approx O(n^2)$$

This means the number of edges grows quadratically with the number of vertices. For an undirected graph, the maximum possible number of edges is:

$$\binom{n}{2} = \frac{n(n-1)}{2}.$$

For a directed graph, the maximum possible number of edges is:

$$n(n - 1).$$

A graph is considered dense when $|E|$ is close to these upper bounds. Dense graphs are common in applications like social networks, transportation networks, or communication networks where most entities are interconnected.

In this paper, we deal with re-calculating the all-pairs shortest path (APSP) matrix after a minor modification of a weighted dense graph, e.g., adding a node, removing a node, or updating an edge. We assume the APSP matrix for the original graph is already known. The graph can be directed or undirected. A straightforward method for calculating the APSP matrix of the updated graph is to use the Floyd–Warshall algorithm to recalculate the updated graph, it needs $O(n^3)$ time. It is a very expensive time cost for a large dense graph. We are trying to utilize the already calculated APSP matrix to make calculation of the new APSP matrix less expensive.

2 RELATED WORK

The Shortest Path Problem (SPP) is a foundational topic in graph theory and optimization, with numerous applications in transportation networks, telecommunications, and logistics [1, 3, 16, 20, 21]. Over the years, various algorithms and techniques have been developed to solve different variants of the problem efficiently.

2.1 Classical Algorithms

One of the earliest contributions to SPP dates back to the work of Dijkstra (1959), who proposed a greedy algorithm to solve the single-source shortest path problem for graphs with non-negative edge weights in $O(|V|^2)$ time, later optimized to $O(|E| + |V| \log |V|)$ using priority queues [6]. The idea of this algorithm is also given in (Leyzorek et al. 1957) [13].

For graphs with negative edge weights, the Bellman-Ford algorithm (1958) provides a reliable solution, albeit with a higher

computational cost of $O(|V||E|)$ [2]. The Floyd-Warshall algorithm (1962) extends these techniques to compute all-pairs shortest paths in $O(|V|^3)$, leveraging dynamic programming [7].

2.2 Optimizations and Modern Variants

Advances in data structures, such as Fibonacci heaps [8], have further improved the efficiency of Dijkstra's algorithm. More recently, heuristic-based approaches like A^* have been widely adopted for real-world applications, where an admissible heuristic guides the search to improve runtime performance [10]. Parallel and distributed versions of shortest path algorithms have also emerged, leveraging modern computing architectures for large-scale graphs [17].

2.3 Specialized Applications

The SPP has been extended to address specialized scenarios, such as the multi-criteria shortest path problem, which considers trade-offs between multiple objectives, like cost and time [9]. In dynamic or time-dependent graphs, the edge weights may vary over time, necessitating new algorithms like the time-expanded shortest path [5]. Additionally, the rise of massive graphs in social networks and geographic information systems has spurred the development of approximate methods, such as graph sparsification and sketching [4].

2.4 Challenges in Dense and Weighted Graphs

For dense graphs, where the number of edges approaches $O(|V|^2)$, naive algorithms often become computationally expensive. Techniques like matrix-based methods for all-pairs shortest paths [11] or GPU-accelerated implementations [12] have shown promise in reducing computational overhead.

2.5 Emerging Trends

Recent research has explored incorporating machine learning into shortest path computations. These methods predict likely paths or edge weights, complementing traditional algorithms in scenarios with incomplete or noisy data [19]. Moreover, shortest path calculations are increasingly being integrated with clustering and community detection tasks to solve problems in network science and biology [18].

3 UPDATING A LARGE GRAPH

In a previous paper, we propose Algorithm 1 (MMJ distance by recursion) for solving the all pairs minimax path problem or widest path problem [14]. It can also be revised to solve the APSP matrix of the shortest path problem, which also takes $O(n^3)$ time.

3.1 APSP after adding a node

As discussed in Section 6.1 (Merit of Algorithm 1) of [15], Algorithm 1 (MMJ distance by recursion) has the advantage of warm-start capability. Consider the scenario where we have already computed the APSP matrix $\mathbb{M}_G$ for a large graph G, and a new point or node, p, which is not part of G, is introduced. The updated graph is referred to as $G + p$. When determining the APSP matrix for $G + p$, conventional algorithms like Floyd–Warshall algorithm or

Johnson's algorithm might necessitate a computation beginning from scratch, which takes $O(n^3)$ time.

Algorithm 1 leverages the precomputed $\mathbb{M}_G$ to facilitate the calculation of the new APSP matrix of graph $G + p$, in accordance with the results of Theorem 3.1, 3.2, 3.5, and Corollary 3.3, 3.4, which are revised from the theorems and corollary in Section 3.3 (Other properties of MMJ distance) of [14]. A warm-start of Algorithm 1 requires only $O(n^2)$ time, which is much less expensive than a cold-start of conventional algorithms, which takes $O(n^3)$ time.

THEOREM 3.1. *Suppose* $r \in \{1, 2, \ldots, n\}$,

$$f(t) = d(G_{n+1}, G_t) + SPD(G_t, G_r \mid G_{[1,n]}) \quad (1)$$

$$\mathbb{X} = \{f(t) \mid t \in \{1, 2, \ldots, n\}\} \quad (2)$$

then,

$$SPD(G_{n+1}, G_r \mid G_{[1,n+1]}) = min(\mathbb{X}) \quad (3)$$

For the meaning of $G_t, G_r, G_{[1,n]}, and\ G_{[1,n+1]}$, see Table 1.

PROOF. There are n possibilities of the shortest path from G_{n+1} to G_r, under the context of $G_{[1,n+1]}$, set $\mathbb{X}$ enumerate them all. Each element of $\mathbb{X}$ is the shortest path distance of each possibility. Therefore, according to the definition of shortest path distance, $SPD(G_{n+1}, G_r \mid G_{[1,n+1]}) = min(\mathbb{X})$. The n possibilities are not mutually exclusive; multiple possibilities can happen simultaneously if the shortest paths are not unique. □

THEOREM 3.2. *Suppose* $r \in \{1, 2, \ldots, n\}$,

$$f(t) = SPD(G_r, G_t \mid G_{[1,n]}) + d(G_t, G_{n+1}) \quad (4)$$

$$\mathbb{X} = \{f(t) \mid t \in \{1, 2, \ldots, n\}\} \quad (5)$$

then,

$$SPD(G_r, G_{n+1} \mid G_{[1,n+1]}) = min(\mathbb{X}) \quad (6)$$

PROOF. The proof is similar to proof of Theorem 3.1. Since we are dealing with a directed graph, the order of nodes in a distance notation matters. □

COROLLARY 3.3. *Suppose* $r \in \{1, 2, \ldots, N\}, p \notin G$,

$$f(t) = d(p, G_t) + SPD(G_t, G_r \mid G) \quad (7)$$

$$\mathbb{X} = \{f(t) \mid t \in \{1, 2, \ldots, N\}\} \quad (8)$$

then,

$$SPD(p, G_r \mid G + p) = min(\mathbb{X}) \quad (9)$$

For the meaning of $G + p$, see Table 1.

PROOF. The proof follows the conclusion of Theorem 3.1. □

COROLLARY 3.4. *Suppose* $r \in \{1, 2, \ldots, N\}, p \notin G$,

$$f(t) = SPD(G_r, G_t \mid G) + d(G_t, p) \quad (10)$$

$$\mathbb{X} = \{f(t) \mid t \in \{1, 2, \ldots, N\}\} \quad (11)$$

then,

$$SPD(G_r, p \mid G + p) = min(\mathbb{X}) \quad (12)$$

PROOF. The proof follows the conclusion of Theorem 3.2. □

Table 1: Table of notations

G	A weighted dense graph of N nodes, with each node indexed from 1 to N. Graph G is supposed to be directed, an undirected graph can be considered as a special case of a directed graph;
$G_{[1,n]}$	A graph that is composed of the first n nodes of G, the nodes are indexed from 1 to n;
G_{n+1}	The $(n + 1)$th node of G;
$G + p$	Graph G plus one new node p. Since $p \notin G$, if G has N nodes, this new graph now has $N + 1$ nodes;
$G - G_k$	A new graph by removing the kth node from graph G. If G has N nodes, this new graph now has $N - 1$ nodes;
G'	A new graph by modifying weight of one edge of graph G, or by removing a node from G, or by adding a node to G;
$\Psi_{(i,j,n,G)}$	$\Psi_{(i,j,n,G)}$ is a sequence from node i to node j, which has a total number of n nodes. All the nodes in the sequence must belong to graph G. That is to say, it is a path starts from i, and ends with j. For convenience, the path is not allowed to have loops, unless the start and the end is the same node;
$d(i, j)$	$d(i, j)$ is the adjacency distance from node i to node j on graph G. Note the graph is directed;
$len(\Psi_{(i,j,n,G)})$	$len(\Psi_{(i,j,n,G)})$ is the length of path $\Psi_{(i,j,n,G)}$, which is the sum of edge weights on the path;
$\Theta_{(i,j,G)}$	$\Theta_{(i,j,G)}$ is the set of all paths from node i to node j. A path in $\Theta_{(i,j,G)}$ can have arbitrary number of nodes (at least two). All the nodes in a path must belong to graph G;
$SPD(i, j \mid G)$	$SPD(i, j \mid G)$ is the shortest path distance (SPD) from node i to node j, where G is the **Context** of the shortest path distance. The **Context** of a distance is defined in [14]. A node's shortest path distance to itself is always 0;
$\mathbb{M}_{k,G_{[1,k]}}$	$\mathbb{M}_{k,G_{[1,k]}}$ is the pairwise shortest path distance matrix of $G_{[1,k]}$, which has shape $k \times k$. The shortest path distances are under the **Context** of $G_{[1,k]}$;
$\mathbb{M}_G$	The APSP matrix of G, $\mathbb{M}_G = \mathbb{M}_{N,G_{[1,N]}}$;

THEOREM 3.5. *Suppose $i, j \in \{1, 2, \ldots, n\}$,*

$$x_1 = SPD(G_i, G_j \mid G_{[1,n]}) \tag{13}$$

$$t_1 = SPD(G_i, G_{n+1} \mid G_{[1,n+1]}) \tag{14}$$

$$t_2 = SPD(G_{n+1}, G_j \mid G_{[1,n+1]}) \tag{15}$$

$$x_2 = t_1 + t_2 \tag{16}$$

then,

$$SPD(G_i, G_j \mid G_{[1,n+1]}) = min(x_1, x_2) \tag{17}$$

PROOF. If the shortest paths are not unique, there are two possibilities for the shortest path from G_i to G_j, under the context of $G_{[1,n+1]}$:

(1) Their exists one shortest path from G_i to G_j which does not contain node G_{n+1}, which means G_{n+1} is not necessary

for the shortest path from G_i to G_j, under the context of $G_{[1,n+1]}$. That is to say:

$$SPD(G_i, G_j \mid G_{[1,n+1]}) = SPD(G_i, G_j \mid G_{[1,n]})$$

(2) All the shortest paths from G_i to G_j must contain node G_{n+1}, which means G_{n+1} is necessary for the shortest path from G_i to G_j, under the context of $G_{[1,n+1]}$. That is to say:

$$SPD(G_i, G_j \mid G_{[1,n+1]}) \neq SPD(G_i, G_j \mid G_{[1,n]})$$

x_1 is the SPD of the first possibility; x_2 is the SPD of the second possibility. Therefore, according to the definition of shortest path distance, $SPD(G_i, G_j \mid G_{[1,n+1]}) = min(x_1, x_2)$. If the shortest path is unique, the reasoning still holds. The two possibilities are mutually exclusive; they cannot happen simultaneously.   □

THEOREM 3.6. *Suppose* $i, j \in \{1, 2, \dots, n\}$,

$$t_1 = SPD(G_i, G_{n+1} \mid G_{[1,n+1]}) \tag{18}$$

$$t_2 = SPD(G_{n+1}, G_j \mid G_{[1,n+1]}) \tag{19}$$

if,

$$SPD(G_i, G_j \mid G_{[1,n+1]}) < t_1 + t_2 \tag{20}$$

then,

$$SPD(G_i, G_j \mid G_{[1,n+1]}) = SPD(G_i, G_j \mid G_{[1,n]}) \tag{21}$$

which means G_{n+1} is not necessary for the shortest path from G_i to G_j, under the context of $G_{[1,n+1]}$.

PROOF. As discussed in the proof of Theorem 3.5, there are two possibilities for the shortest path from G_i to G_j, under the context of $G_{[1,n+1]}$. And the two possibilities are mutually exclusive; they cannot happen simultaneously. We only need to negate possibility (2), then we can arrive to the conclusion of Equation 21. Suppose possibility (2) happens, then G_{n+1} is necessary for the shortest path from G_i to G_j, under the context of $G_{[1,n+1]}$. Then $SPD(G_i, G_j \mid G_{[1,n+1]}) = t_1 + t_2$, which is contradicted to Equation 20. Therefore, possibility (2) cannot happen; only possibility (1) can happen. □

3.2 APSP after removing a node

Sometimes, we need to remove a node from a large graph. Suppose we removed the kth node from graph G, the new graph is noted $G - G_k$ (Table 1). A cold-start of conventional algorithms for calculating the APSP matrix of graph $G - G_k$ will take $O(n^3)$ time.

However, we can take a smarter method to make the computation less expensive. Firstly, we make a *need_update_list* to record which nodes' shortest path distance (SPD) to others are affected by the deletion. E.g., in Figure 1, if we delete Node C, we get Figure 2 (since the matrices are symmetric, we only show half of them). Removing a node is equivalent to set the node's distances (to and from) to other nodes to infinity. The *need_update_list* is totally empty for Figure 2. Because none of the pair-wise shortest path distances are affected by removing Node C. Except Node C itself. E.g.,

$$SPD(A, B \mid G) = SPD(A, B \mid G - C)$$
$$SPD(A, D \mid G) = SPD(A, D \mid G - C)$$
$$SPD(B, A \mid G) = SPD(B, A \mid G - C)$$
$$SPD(B, D \mid G) = SPD(B, D \mid G - C)$$
$$SPD(D, A \mid G) = SPD(D, A \mid G - C)$$
$$SPD(D, B \mid G) = SPD(D, B \mid G - C)$$

The *need_update_list* for Figure 2 looks like this:

$$Node\ A : empty$$
$$Node\ B : empty$$
$$Node\ D : empty$$

In Figure 3, we removed Node B. Some of the remaining pair-wise shortest path distances are affected, some are not. E.g.,

$$SPD(A, C \mid G) \neq SPD(A, C \mid G - B)$$
$$SPD(A, D \mid G) \neq SPD(A, D \mid G - B)$$
$$SPD(C, A \mid G) \neq SPD(C, A \mid G - B)$$
$$SPD(C, D \mid G) = SPD(C, D \mid G - B)$$
$$SPD(D, A \mid G) \neq SPD(D, A \mid G - B)$$
$$SPD(D, C \mid G) = SPD(D, C \mid G - B)$$

The *need_update_list* for Figure 3 looks like this:

$$Node\ A : \ [A,\ C],\ [A,\ D]$$
$$Node\ C : \ [C,\ A]$$
$$Node\ D : \ [D,\ A]$$

We use Theorem 3.6 to construct the *need_update_list*, by setting the node to be removed as G_{n+1}. Constructing the *need_update_list* only needs $O(n^2)$ time.

Definition 3.7. Cost for calculating the new APSP matrix after removing node G_k from G.

$$C(G, \mathbb{M}_G, G_k) = \frac{\Phi(\mathbb{M}_G, G_k)}{N - 1} \tag{22}$$

Where $\mathbb{M}_G$ is the APSP matrix of graph G; G_k is the node to be removed; $\Phi(\mathbb{M}_G, G_k)$ is the number of non-empty items in the *need_update_list*, after removing node G_k from G; N is the number of vertices in graph G. The range of $C(G, \mathbb{M}_G, G_k)$ is $[0, 1]$.

We devise an algorithm for solving the APSP matrix after removing a node. In Algorithm 5, we first construct the *need_update_list* after removing node G_k, then use the *need_update_list* to calculate the *Cost* defined in Definition 3.7. If the *Cost* is larger than hyper-parameter δ, we just use the Floyd-Warshall algorithm to re-calculate the APSP matrix of the new graph $G - G_k$. If the *Cost* is small, we use Dijkstra's algorithm to calculate a node's distance to other nodes in the new graph $G - G_k$. Hopefully, only a few nodes will be affected by removing node G_k, therefore, saved time for calculating the new APSP matrix.

So, removing a node from a graph is harder than adding a node to the graph, for calculating the APSP matrix. Adding a node only needs $O(n^2)$ time even for the worst case. For removing a node, the best case complexity is $O(n^2)$, the worst case complexity is $O(n^3)$. E.g., in the *need_update_list* for Figure 2, all the items are empty, the complexity for solving the new is APSP matrix $O(n^2)$, which is used for calculating the *need_update_list*. In the *need_update_list* for Figure 3, all the items are non-empty, the complexity is $O(n^3)$.

3.3 APSP after modifying an edge

Modifying an edge can be accomplished by removing one of the edge's vertices, then add the node back, with the edge being updated. So, the best case complexity for modifying an edge is $O(n^2)$, the worst case complexity is $O(n^3)$; the same complexity as removing a node.

Algorithm 6 is devised to calculate the APSP matrix after modifying an edge. It firstly remove a node associated with the edge from the graph, then add the node back, with the edge being updated. An edge is associated with two nodes. So, before removing a node,

it calculates which node is cheaper to remove, then remove the cheaper one.

4 TESTING OF THE ALGORITHMS

We tested the algorithms for warm-start calculation of the new APSP matrix after a minor update of a dense graph, e.g., removing a node, or modifying an edge. All the code in the experiments is implemented with Python.

4.1 Experiment I

In Experiment I, we test warm-start calculation of the new APSP matrix after removing a node, and compare with cold-start calculation of the Floyd-Warshall algorithm and Dijkstra's algorithm. In the experiment, a random node is removed from a complete graph, then record the time spent for calculating the new APSP matrix, by warm-start calculation of Algorithm 5 and cold-start of other algorithms. The ratio of the used time is calculate with Equation 23. Different sizes of graphs are tested, from 100 nodes to 1,000 nodes. For each size of graph, we repeat the experiment three times and

Algorithm 5 APSP after removing a node

Input: G, APSP of G: $\mathbb{M}_G$, node to be removed: G_k, hyper-parameter: δ
Output: $APSP\ of\ G - G_k : \mathbb{M}_{G-G_k}$

1: **function** APSP_REMOVE_NODE($G, \mathbb{M}_G, G_k, \delta$)
2:     $\mathbb{M}_{G-G_k} \leftarrow copy(\mathbb{M}_G)$
3:     $remaining\_node\_list \leftarrow G - G_k$
4:     $need\_update\_list \leftarrow cal\_need\_update\_list(G_k, \mathbb{M}_G)$
5:     $Cost \leftarrow cal\_cost\_of\_remove(need\_update\_list)$
6:     **if** $Cost > \delta$ **then**
7:         $\mathbb{M}_{G-G_k} \leftarrow Floyd\_Warshall(G - G_k)$
8:         **return** $\mathbb{M}_{G-G_k}$
9:     **end if**
10:     **for** i in $remaining\_node\_list$ **do**
11:         **if** $len(need\_update\_list[i]) > 1$ **then**
12:             $temp \leftarrow dijkstra\_one\_to\_all\_others(G - G_k, i)$
13:             **for** j in $need\_update\_list[i]$ **do**
14:                 $\mathbb{M}_{G-G_k}[i, j] \leftarrow temp[j]$
15:             **end for**
16:         **else if** $len(need\_update\_list[i]) > 0$ **then**
17:             $j \leftarrow need\_update\_list[i][0]$
18:             $\mathbb{M}_{G-G_k}[i, j] \leftarrow dijkstra\_one\_to\_one(G - G_k, i, j)$
19:         **else**
20:             $pass$
21:         **end if**
22:     **end for**
23:     **return** $\mathbb{M}_{G-G_k}$
24: **end function**

Algorithm 6 APSP after modifying an edge

Input: G, APSP of G: $\mathbb{M}_G$, edge nodes: e_n, edge weight: e_w, hyper-parameter: δ
Output: APSP of new graph $G' : \mathbb{M}_{G'}$

1: **function** APSP_MODIFY_EDGE($G, \mathbb{M}_G, e_n, e_w, \delta$)
2:     $i \leftarrow e_n[0]$
3:     $j \leftarrow e_n[1]$
4:     $Cost\_i \leftarrow cal\_cost\_of\_remove(G, i)$
5:     $Cost\_j \leftarrow cal\_cost\_of\_remove(G, j)$
6:     **if** $Cost\_i < Cost\_j$ **then**
7:         $G_k \leftarrow i$
8:     **else**
9:         $G_k \leftarrow j$
10:     **end if**
11:     //calculate APSP matrix after removing node.
12:     $\mathbb{M}_{G-G_k} \leftarrow APSP\_remove\_node(G, \mathbb{M}_G, G_k, \delta)$
13:     //Add the node back, update the edge, then use warm-start of Algorithm 1 (MMJ distance by recursion) to calculate the new APSP matrix.
14:     $G' \leftarrow cal\_updated\_graph(G, e_n, e_w)$
15:     $\mathbb{M}_{G'} \leftarrow APSP\_add\_node(G', \mathbb{M}_{G-G_k})$
16:     **return** $\mathbb{M}_{G'}$
17: **end function**

Table 2: Warm-start vs. cold-start calculation of the APSP matrix, after removing a node.

	N = 100	N = 200	N = 500	N = 1000	Avg
Floyd-Warshall	0.18	0.15	0.2	0.1	0.16
Dijkstra	0.51	0.37	0.54	0.76	0.54

Table 3: Warm-start vs. cold-start calculation of the APSP matrix, after modifying an edge.

	N = 100	N = 200	N = 500	N = 1000	Avg
Floyd-Warshall	0.13	0.1	0.17	0.03	0.11
Dijkstra	0.4	0.38	0.49	0.46	0.43

calculate the average of the ratios.

$$r = \frac{APSP_{warm}(G')}{APSP_{cold}(G')} \tag{23}$$

As shown in Table 2, a warm-start calculation only needs 0.16 of the time, to a cold-start calculation with the Floyd-Warshall algorithm on average. That means we can save 84% of calculation time if using warm-start calculation. When compared with Dijkstra's algorithm, the average ratio is 0.54.

4.2 Experiment II

The setting of Experiment II is similar to Experiment I, except that we are testing modifying an edge, not removing a node. As shown in Table 3, we can save 89% of calculation time if using warm-start calculation, when compared with the Floyd-Warshall algorithm; and save 57% of calculation time, when compared with Dijkstra's algorithm.

5 DISCUSSION

The algorithms can be revised to solve the all pairs minimax path problem or widest path problem, after a minor update of a large dense graph.

6 CONCLUSION

We propose two algorithms for warm-start calculation of the all-pairs shortest path (APSP) matrix after a minor modification of a weighted dense graph, e.g., adding a node, removing a node, or updating an edge. We assume the APSP matrix for the original graph is already known, and try to warm-start from the known APSP matrix to reach the new APSP matrix. A cold-start calculation of the APSP matrix for the updated graph needs $O(n^3)$ time. It is a very expensive time cost for a large dense graph. We are trying to utilize the already calculated APSP matrix to make calculation of the new APSP matrix less expensive. The best case complexity for a warm-start calculation is $O(n^2)$, the worst case complexity is $O(n^3)$.

We implemented the algorithms and tested their performance with experiments. The result shows a warm-start calculation can save about 84% of calculation time when compared with the Floyd-Warshall algorithm; when compared with Dijkstra's algorithm, we

can save 46% of calculation time, for calculating the APSP matrix after removing a node. When the operation is updating an edge, the proportion of saved time is 89%, when compared with the Floyd-Warshall algorithm; and 57% when compared with Dijkstra's algorithm.
